ABSTRACT

Highly functionalized carbonaceous materials were produced by means of the hydrothermal carbonization of cellulose at temperatures in the 220–250 °C range. The formation of this material follows essentially the path of a dehydration process, similar to that previously observed for the hydrothermal transformation of saccharides such as glucose, sucrose or starch. The materials so formed are composed of agglomerates of carbonaceous microspheres (size ~2–5 μm), as evidenced by SEM. The combination of the results of the elemental analysis with that obtained by different spectroscopic techniques (infrared and Raman spectroscopy, and XPS) has allowed us to infer that, from a chemical point of view, the solid product consists of small clusters of condensed benzene rings that form stable groups with oxygen in the core (i.e. ether, quinone, pyrone), whereas the shell possesses more reactive/hydrophilic oxygen functionalities (i.e. hydroxyl, carbonyl, carboxylic, ester).

1. Introduction

The thermal treatment of water mixed with organic substances such as saccharides (glucose, sucrose or starch) or simpler compounds such as furfural at temperatures in the 150–350 °C range (autogenous pressure) gives rise to watersoluble organic substances and a carbon-rich solid product. This process, termed hydrothermal carbonization, has generated widespread interest in recent years [1–6]. However, the hydrothermal treatment of saccharides is not a new process. Experiments involving the hydrothermal carbonization of different types of saccharides were carried out during the first half of the twentieth century in order to obtain information about the mechanism of natural coalification [7–9]. Later on, numerous papers dealing with the hydrothermal treatment of cellulose to obtain liquid fuel or chemicals appeared [10–14]. Not until recently, however, has any attention been paid to the solid residue resulting from this treatment. Wang et al. were the first to report on the hydrothermal treatment of sucrose as a way to produce carbonaceous microspheres (size ~1.5 μm) [1]. Subsequently, Sun and Li reported on the preparation of carbonaceous microspheres of a tunable size (0.2–1.5 μm) loaded with noble-metal nanoparticles [3]. Other groups have taken advantage of the oxygen functionalities present on the outer surface of the carbonaceous microspheres and employed them as sacrificial templates to fabricate hollow spheres of inorganic materials (Ga2O3, GaN, WO3, SnO2, etc.) [3,15–19]. We have previously investigated the use of carbonaceous microspheres produced by the hydrothermal carbonization of glucose, sucrose and starch as precursors for the production of graphitic carbon nanostructures and the application of these nanocarbons as catalyst supports [20,21].

Among the potential saccharides that can be employed to produce carbonaceous materials through hydrothermal carbonization, cellulose is the most promising material as it is by far the most abundant and inexpensive saccharide available. Although several authors have reported using cellulose...
for the production of carbon materials by means of pyrolysis at high temperatures [22–24], to the best of our knowledge, no one has employed cellulose to produce carbonaceous materials by means of hydrothermal carbonization. In the present work we investigate the potential of cellulose as precursor for the production of highly functionalized carbonaceous materials via hydrothermal carbonization. The chemical and structural characteristics of the hydrothermally carbonized products are also investigated.

2. Experimental

2.1. Hydrothermal treatment of cellulose

The hydrothermal carbonization of cellulose was carried out according to the following procedure. Between 2 and 16 g of cellulose (Aldrich) was dispersed in water (50 mL) and stirred for 4 h. The ratio volume of solution/volume of autoclave is around 0.3. The mixture was then transferred to a stainless steel autoclave fitted with a stirring mechanism, heated up to a temperature in the 200–250 °C range and maintained at this temperature for 2 or 4 h. The resulting solid product (here denoted as hydrochar) was recovered by filtration and washed with abundant distilled water. Then, it was dried at 120 °C for 4 h. The experimental conditions (concentration, temperature and time) used in these experiments are listed in Table 1. The codes used to identify the hydrochar samples are also indicated in this table.

2.2. Characterization methods

Scanning electron microscopy (SEM) microphotographs were obtained with a Zeiss DSM 942 microscope. Diffuse reflectance infrared (IR) spectra of the powders of the materials were recorded on a Nicolet Magna-IR 560 spectrometer fitted with a diffuse reflection attachment. The Raman spectra were recorded on a Horiva (LabRam HR-800) spectrometer. The IR spectra were obtained with a Zeiss DSM 942 microscope. Diffuse reflectance infrared (IR) spectra of the powders of the materials were measured by setting C 1s to 284.6 eV. Adsorption measurements were performed using an ASAP 2020 (Micromeritics) volumetric adsorption system. The thermogravimetric experiments were carried out in a C.I. Electronics analyser. Elemental analysis (C, H and O) of the samples was carried out on a LECO CHN-932 microanalyzer.

3. Results and discussion

3.1. Structural properties

Fig. 1 shows SEM images of the cellulose (Fig. 1a) and products obtained by hydrothermal treatment at 210 °C (Fig. 1b), 220 °C (Fig. 1c), 230 °C (Fig. 1d) and 250 °C (Fig. 1e and f). It should be noted that, whereas the products from hydrothermal treatment at 210 °C exhibit an irregular morphology similar to that of pristine cellulose, the samples obtained at temperatures ≥220 °C consist mainly of aggregates of microspheres with a diameter in the 2–10 μm range. The SEM images (Fig. 1) evidence that there is an abrupt morphological change in the 210–220 °C range. These results suggest that the onset of the hydrothermal reactions for the cellulose occurs at around 220 °C. This conclusion is confirmed by the effect that hydrothermal treatment has upon the microcrystalline structure of cellulose. Thus, pristine cellulose exhibits three characteristic peaks, as shown in Fig. 2. The (1 0 1) and (0 0 2) reflections are caused by the transverse arrangement of the crystallites in cellulose I, while reflection (0 0 4) is related to the longitudinal structure of the polymer [25]. It is observed that when cellulose is hydrothermally treated at 210 °C, the resulting material exhibits a XRD pattern similar to that of pristine cellulose, indicating that the microcrystalline structure of the cellulose has been preserved. In contrast, the samples obtained at temperatures ≥220 °C are no longer crystalline, as can be deduced from the absence of reflections in the XRD pattern (see Fig. 2). These results evidence that the onset of hydrothermal carbonization takes place at around 220 °C. This is also confirmed by the FTIR spectra corresponding to the hydrochar samples obtained at different temperatures, as will be discussed in the next section. The temperature for the onset of hydrothermal carbonization of cellulose is considerably higher than for glucose, sucrose or starch (160–170 °C) [26,27]. The strong resistance of the cellulose to decompose is a consequence of the fact that the hydroxyl

* The yield is expressed as: g product/100 g cellulose. The percentage of C contained in the cellulose that is retained in the carbonized products is indicated in parentheses.
groups of the glucose residues present in the structure of the cellulose form hydrogen bonds that hold the polymeric chains firmly together and side-by-side [28,29].

Analysis of the textural properties of the cellulose-derived hydrochar samples shows that they have a poor porosity, as evidenced by the N2 adsorption isotherm obtained for the CE-2 sample (see Fig. S1 in Supplementary data). This sample has a BET surface area of 30 m² g⁻¹, which matches well with the external surface area determined by the a-s-plot technique (26 m² g⁻¹) (see inset in Fig. S1).

3.2. Chemical characteristics

The hydrothermal carbonization of the cellulose leads to an increase in the carbon content of the solid residue from 44.4 wt.% (cellulose) to 70.7–72.5 wt.% in the hydrochar samples (see Table 1). At the same time, there is a reduction in the oxygen and hydrogen contents. These variations are consistent with the formation of a well-condensed material. Thus, analysis of the change in weight loss (Fig. S2a) and the rate of weight loss (Fig. S2b) with temperature (measured...
under an inert atmosphere) for the hydrochar samples shows that the decomposition of this material takes place in a temperature range of \(24^\circ\text{C} \approx 300 \text{–} 700^\circ\text{C}\), which is typical of highly condensed carbonaceous materials such as coal [30]. This behaviour contrasts with that observed for the pyrolysis of pure cellulose, which occurs suddenly at the relatively low temperature of \(\approx 300^\circ\text{C}\) (see Fig. S2). It was also observed that an increase in the temperature of hydrothermal carbonization (i.e. from \(230^\circ\text{C}\) to \(250^\circ\text{C}\)) causes a decrease in the O/C and H/C atomic ratios (see Table 1), suggesting an increase in the degree of condensation of the hydrochar products. Moreover, shorter reaction times or higher concentrations of cellulose lead to less condensed products (high O/C and H/C atomic ratios). The variation in the elemental composition of the materials (from cellulose to hydrochar products) was analyzed with the aid of the Van Krevelen diagram (see Fig. 3) [31], which shows that the evolution of the H/C–O/C atomic ratios from cellulose to hydrochar follows essentially the path of a dehydration process, similar to that previously observed for the hydrothermal transformation of saccharides such as glucose, sucrose or starch [26].

The product yields (grams of hydrochar per 100 grams of cellulose) obtained from the hydrothermal carbonization are in the 30–50 wt.% range (see Table 1). The percentages of carbon retained in the final solid product are also listed in Table 1. It can be seen that, depending on the operational conditions, the carbon present in the cellulose retained in the hydrochar products is in the 54–84 wt.% range, while the rest mainly remains in the organic compounds that are dissolved in the aqueous phase (i.e. furfural, 5-hydroxymethylfurfural, organic acids, aldehydes, etc.) [32–35]. It should be noted that for a carbonization temperature of \(250^\circ\text{C}\) and high concentrations of cellulose (>160 g L\(^{-1}\)), the percentage of carbon fixed in the hydrochar is \(\approx 70\text{–}80\%\). Taking into account the recalcitrant nature of carbon contained in the hydrochar (high resistance to be mineralised due to the microbial action), the above result suggests that the hydrothermal carbonization of cellulose is an effective way to increases the turnover time of the carbon contained in the biomass.

The chemical transformations that occur when the cellulose is converted into carbonaceous products by means of hydrothermal carbonization were examined by several spectroscopic techniques. FTIR spectra of the hydrochar samples and cellulose are shown in Fig. 4. It can be seen that the FTIR spectra of the sample hydrothermally treated at \(210^\circ\text{C}\) is similar to that of the cellulose, confirming that no chemical transformation occurs when the cellulose is heat-treated at \(< 220^\circ\text{C}\). In contrast, the samples obtained at \(> 220^\circ\text{C}\) exhibit completely different FTIR traces (see Fig. 4). The spectra corresponding to the hydrochar samples obtained at \(\geq 220^\circ\text{C}\) are very similar. They contain several bands which reveal that

**Fig. 2** – XRD patterns for (a) pristine cellulose and for the samples hydrothermally treated at (b) \(210^\circ\text{C}\) and (c) \(220^\circ\text{C}\).

**Fig. 3** – (H/C)–(O/C) Van Krevelen diagram. This shows the (H/C) vs. (O/C) atomic ratios for: (a) cellulose and other saccharides, (b) the hydrochar products obtained from cellulose and (c) the carbonized material resulting from the pyrolysis of the cellulose at \(700^\circ\text{C}\) (CE-c).
Aromatization processes take place during hydrothermal carbonization. The presence of aromatic rings is also evidenced by the band at 1620 cm\(^{-1}\), attributed to C\(_\text{C}\) vibrations [27,32], and to the bands in the 875–750 cm\(^{-1}\) region, assigned to aromatic C\(_\text{A}\)H out-of-plane bending vibrations [36]. These hydrochar materials also possess aliphatic structures, as can be deduced from the band at 3000–2815 cm\(^{-1}\), which corresponds to stretching vibrations of aliphatic C\(_\text{A}\)H [37,38].

Moreover, the presence of oxygen groups is suggested by the bands at: 3000–3700 cm\(^{-1}\) (a wide band attributed to O\(_\text{A}\)H stretching vibrations in hydroxyl or carboxyl groups) [37], 1710 cm\(^{-1}\) (C=O vibrations corresponding to carbonyl, quinone, ester or carboxyl) [35] and 1000–1460 cm\(^{-1}\) (C\(_\text{A}\)O stretching vibrations in hydroxyl, ester or ether and O\(_\text{H}\) bending vibrations) [35]. The decrease (in relation to raw cellulose) in the intensity of the bands at 1000–1460 cm\(^{-1}\) and the broad band at 3000–3700 cm\(^{-1}\) suggest that dehydration occurred during the hydrothermal carbonization of the cellulose, confirming our analysis of the evolution of the O/C–H/C atomic ratios based on the Van Krevelen diagram (see Fig. 3).

In order to check the presence of aromatic structures in the hydrochar products, Raman spectroscopy analysis was performed. The Raman spectrum obtained for the CE-4 hydrochar sample is presented in Fig. 5a. For purposes of comparison, the same figure shows the spectrum obtained for the CE-4 sample carbonized at 800 °C (1 h, N\(_2\) atmosphere). Both spectra are characteristic of carbonized materials [39,40] and they differ completely from that of the cellulose (see inset of Fig. 5a). Thus, the carbonized samples exhibit two broad overlapping bands at around 1360 (D-mode) and 1587 (G-mode) cm\(^{-1}\), which reveal the presence of C sp\(^2\) atoms in benzene or condensed benzene rings of amorphous (partially hydrogenated) carbon [41,42]. Small aromatic clusters must therefore be present in the hydrochar samples. This corroborates the presence of aromatic structures in the hydrochar materials and in turn confirms the results deduced by FTIR.

The oxygen functional groups present on the outer layer of the hydrochar particles were investigated by X-ray photoelectron spectroscopy (XPS). A representative C 1s core level spectrum obtained for the CE-3 is shown in Fig. 5b. The C 1s spectrum of the rest of the samples is similar to the one showed. It contains four signals attributed, respectively, to the aliphatic/aromatic carbon group (CH\(_x\), C–C/C=C) (284.6 eV), hydroxyl groups (OH) (285.7 eV), carbonyl groups (>C=O) (287.3 eV) and carboxylic groups, esters or lactones (>COOR) (289.2 eV) [43–45]. These results show that there is an abundance of oxygen groups in the shells of the particles. A comparison of the (O/C) atomic ratios determined by elemental analysis (see Table 1) with those calculated by XPS (0.282 and 0.275 for the CE-2 and CE-3 samples, respectively) shows that the (O/C) atomic ratios in the core and in the shell of the particles are quite similar. This indicates that there is a high concentration of oxygen in the inner part of cellulose.
the hydrochar particles. We believe that the oxygen groups present in the core differ from those in the shell. Whereas the oxygen in the core forms stable groups (i.e. ether, quinone, pyrone, etc.), whereas the oxygen functionalities in the outer layer consist of more reactive/hydrophilic groups (i.e. hydroxyl, carbonyl, carboxylic, ester, etc.), as reflect in the XPS analysis.

### 3.3. The formation of hydrochar from cellulose

There are numerous works on the chemical transformations that take place when cellulose is treated under pressure in sub- or supercritical water in the literature [46-48]. From this information it is possible to reconstruct the mechanism of the formation of hydrochar products from cellulose. This is sche-

![Figure 6 - Mechanism of formation of hydrochar particles from cellulose by hydrothermal carbonization.](image-url)
In summary, we have presented a procedure for obtaining a carbonaceous product, denoted here as hydrochar, by means of the hydrothermal carbonization of cellulose. The hydrochar is made up of micrometer sized spheres (size ~2–10 μm). The onset of carbonization under hydrothermal conditions takes place between 210 °C and 220 °C. From a chemical point of view, the hydrochar contains a high amount of oxygen (~23–24 wt.% of oxygen), which is present both in the core and in the shell of the carbonaceous microspheres. However, the nature of the oxygen groups in the core and shell differs, as inferred from XPS and FTIR measurements. Indeed, the oxygen in the inner part of the microspheres probably consists of less reactive groups (i.e. ether, quinone, pyrone), whereas the shell mainly contains more reactive/ hydrophilic (i.e. hydroxyl, carbonyl, carboxylic, ester) oxygen functionalities.

According to the mechanism proposed here, the formation of hydrochar takes place via: (i) hydrolysis of cellulose chains, (ii) dehydration and fragmentation into soluble products of the monomers that come from the hydrolysis of cellulose, (iii) polymerization or condensation of the soluble products, (iv) aromatization of the polymers thus formed, (v) appearance of a short burst of nucleation and (vi) growth of the nuclei so formed by diffusion and linkage of species from the solution to the surface of the nuclei.
